

## 6.7 — Introduction to pointers

BY ALEX ON JULY 10TH, 2007 | LAST MODIFIED BY ALEX ON JANUARY 23RD, 2020

In lesson **1.3 -- a first look at variables**, we noted that a variable is a name for a piece of memory that holds a value. When our program instantiates a variable, a free memory address is automatically assigned to the variable, and any value we assign to the variable is stored in this memory address.

For example:

```
1 | int x;
```

When this statement is executed by the CPU, a piece of memory from RAM will be set aside. For the sake of example, let's say that the variable `x` is assigned memory location 140. Whenever the program sees the variable `x` in an expression or statement, it knows that it should look in memory location 140 to get the value.

The nice thing about variables is that we don't need to worry about what specific memory address is assigned. We just refer to the variable by its given identifier, and the compiler translates this name into the appropriately assigned memory address.

However, this approach has some limitations, which we'll discuss in this and future lessons.

### The address-of operator (&)

The address-of operator (&) allows us to see what memory address is assigned to a variable. This is pretty straightforward:

```
1 | #include <iostream>
2 |
3 | int main()
4 | {
5 |     int x = 5;
6 |     std::cout << x << '\n'; // print the value of variable x
7 |     std::cout << &x << '\n'; // print the memory address of variable x
8 |
9 |     return 0;
10| }
```

On the author's machine, the above program printed:

```
5
0027FEA0
```

Note: Although the address-of operator looks just like the bitwise-and operator, you can distinguish them because the address-of operator is unary, whereas the bitwise-and operator is binary.

### The dereference operator (\*)

Getting the address of a variable isn't very useful by itself.

The dereference operator (\*) allows us to access the value at a particular address:

```
1 | #include <iostream>
2 |
3 | int main()
4 | {
5 |     int x = 5;
6 |     std::cout << x << '\n'; // print the value of variable x
```

```

7   std::cout << &x << '\n'; // print the memory address of variable x
8   std::cout << *(&x) << '\n'; /// print the value at the memory address of variable x (paren
9
10  return 0;
11  }

```

On the author's machine, the above program printed:

```

5
0027FEA0
5

```

Note: Although the dereference operator looks just like the multiplication operator, you can distinguish them because the dereference operator is unary, whereas the multiplication operator is binary.

## Pointers

With the address-of operator and dereference operators now added to our toolkits, we can now talk about pointers. A **pointer** is a variable that holds a *memory address* as its value.

Pointers are typically seen as one of the most confusing parts of the C++ language, but they're surprisingly simple when explained properly.

### Declaring a pointer

Pointer variables are declared just like normal variables, only with an asterisk between the data type and the variable name. Note that this asterisk is *not* a dereference. It is part of the pointer declaration syntax.

```

1  int *iPtr; // a pointer to an integer value
2  double *dPtr; // a pointer to a double value
3
4  int* iPtr2; // also valid syntax (acceptable, but not favored)
5  int * iPtr3; // also valid syntax (but don't do this)
6
7  int *iPtr4, *iPtr5; // declare two pointers to integer variables

```

Syntactically, C++ will accept the asterisk next to the data type, next to the variable name, or even in the middle.

However, when declaring multiple pointer variables, the asterisk has to be included with each variable. It's easy to forget to do this if you get used to attaching the asterisk to the type instead of the variable name!

```

1  int* iPtr6, iPtr7; // iPtr6 is a pointer to an int, but iPtr7 is just a plain int!

```

For this reason, when declaring a variable, we recommend putting the asterisk next to the variable name.

*Best practice: When declaring a pointer variable, put the asterisk next to the variable name.*

However, when returning a pointer from a function, it's clearer to put the asterisk next to the return type:

```

1  int* doSomething();

```

This makes it clear that the function is returning a value of type `int*` and not an `int`.

*Best practice: When declaring a function, put the asterisk of a pointer return value next to the type.*

Just like normal variables, pointers are not initialized when declared. If not initialized with a value, they will contain garbage.

One note on pointer nomenclature: "X pointer" (where X is some type) is a commonly used shorthand for "pointer to an X". So when we say, "an integer pointer", we really mean "a pointer to an integer".

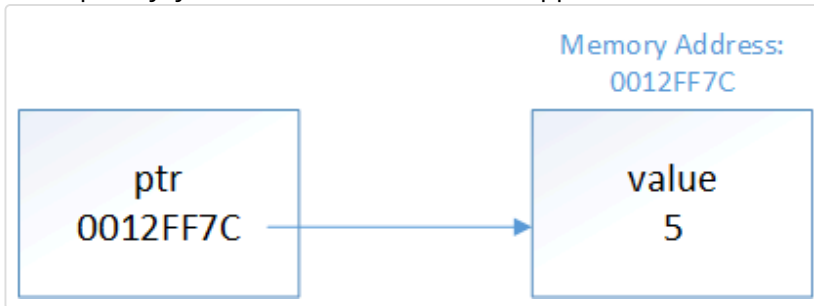

## Assigning a value to a pointer

Since pointers only hold addresses, when we assign a value to a pointer, that value has to be an address. One of the most common things to do with pointers is have them hold the address of a different variable.

To get the address of a variable, we use the address-of operator:

```
1 | int v = 5;
2 | int *ptr = &v; // initialize ptr with address of variable v
```

Conceptually, you can think of the above snippet like this:

This is where pointers get their name from -- ptr is holding the address of variable value, so we say that ptr is “pointing to” v.

It is also easy to see using code:

```
1 | #include <iostream>
2 |
3 | int main()
4 | {
5 |     int v = 5;
6 |     int *ptr = &v; // initialize ptr with address of variable v
7 |
8 |     std::cout << &v << '\n'; // print the address of variable v
9 |     std::cout << ptr << '\n'; // print the address that ptr is holding
10 |
11 |     return 0;
12 | }
```

On the author’s machine, this printed:

```
0012FF7C
0012FF7C
```

The type of the pointer has to match the type of the variable being pointed to:

```
1 | int iValue = 5;
2 | double dValue = 7.0;
3 |
4 | int *iPtr = &iValue; // ok
5 | double *dPtr = &dValue; // ok
6 | iPtr = &dValue; // wrong -- int pointer cannot point to the address of a double variable
7 | dPtr = &iValue; // wrong -- double pointer cannot point to the address of an int variable
```

Note that the following is also not legal:

```
1 | int *ptr = 5;
```

This is because pointers can only hold addresses, and the integer literal 5 does not have a memory address. If you try this, the compiler will tell you it cannot convert an integer to an integer pointer.

C++ will also not allow you to directly assign literal memory addresses to a pointer:

```
1 | double *dPtr = 0x0012FF7C; // not okay, treated as assigning an integer literal
```

### The address-of operator returns a pointer

It's worth noting that the address-of operator (&) doesn't return the address of its operand as a literal. Instead, it returns a pointer containing the address of the operand, whose type is derived from the argument (e.g. taking the address of an int will return the address in an int pointer).

We can see this in the following example:

```
1 | #include <iostream>
2 | #include <typeinfo>
3 |
4 | int main()
5 | {
6 |     int x(4);
7 |     std::cout << typeid(&x).name();
8 |
9 |     return 0;
10 | }
```

On Visual Studio 2013, this printed:

```
int *
```

(With gcc, this prints "pi" (pointer to int) instead).

This pointer can then be printed or assigned as desired.

### Dereferencing pointers

Once we have a pointer variable pointing at something, the other common thing to do with it is dereference the pointer to get the value of what it's pointing at. A dereferenced pointer evaluates to the *contents* of the address it is pointing to.

```
1 | int value = 5;
2 | std::cout << &value; // prints address of value
3 | std::cout << value; // prints contents of value
4 |
5 | int *ptr = &value; // ptr points to value
6 | std::cout << ptr; // prints address held in ptr, which is &value
7 | std::cout << *ptr; // dereference ptr (get the value that ptr is pointing to)
```

The above program prints:

```
0012FF7C
5
0012FF7C
5
```

This is why pointers must have a type. Without a type, a pointer wouldn't know how to interpret the contents it was pointing to when it was dereferenced. It's also why the type of the pointer and the variable address it's being assigned to must match. If they did not, when the pointer was dereferenced, it would misinterpret the bits as a different type.

Once assigned, a pointer value can be reassigned to another value:

```
1 | int value1 = 5;
```

```

2   int value2 = 7;
3
4   int *ptr;
5
6   ptr = &value1; // ptr points to value1
7   std::cout << *ptr; // prints 5
8
9   ptr = &value2; // ptr now points to value2
10  std::cout << *ptr; // prints 7

```

When the address of variable value is assigned to ptr, the following are true:

- ptr is the same as &value
- \*ptr is treated the same as value

Because \*ptr is treated the same as value, you can assign values to it just as if it were variable value! The following program prints 7:

```

1   int value = 5;
2   int *ptr = &value; // ptr points to value
3
4   *ptr = 7; // *ptr is the same as value, which is assigned 7
5   std::cout << value; // prints 7

```

### A warning about dereferencing invalid pointers

Pointers in C++ are inherently unsafe, and improper pointer usage is one of the best ways to crash your application.

When a pointer is dereferenced, the application attempts to go to the memory location that is stored in the pointer and retrieve the contents of memory. For security reasons, modern operating systems sandbox applications to prevent them from improperly interacting with other applications, and to protect the stability of the operating system itself. If an application tries to access a memory location not allocated to it by the operating system, the operating system may shut down the application.

The following program illustrates this, and will probably crash when you run it (go ahead, try it, you won't harm your machine):

```

1   #include <iostream>
2
3   void foo(int *&p)
4   {
5       // p is a reference to a pointer. We'll cover references (and references to pointers) lat
6       // We're using this to trick the compiler into thinking p could be modified, so it won't c
7       // This isn't something you'll ever want to do intentionally.
8   }
9
10  int main()
11  {
12      int *p; // Create an uninitialized pointer (that points to garbage)
13      foo(p); // Trick compiler into thinking we're going to assign this a valid value
14
15      std::cout << *p; // Dereference the garbage pointer
16
17      return 0;
18  }

```

### The size of pointers

The size of a pointer is dependent upon the architecture the executable is compiled for -- a 32-bit executable uses 32-bit memory addresses -- consequently, a pointer on a 32-bit machine is 32 bits (4 bytes). With a 64-bit

executable, a pointer would be 64 bits (8 bytes). Note that this is true regardless of what is being pointed to:

```

1  char *chPtr; // chars are 1 byte
2  int *iPtr; // ints are usually 4 bytes
3  struct Something
4  {
5      int nX, nY, nZ;
6  };
7  Something *somethingPtr; // Something is probably 12 bytes
8
9  std::cout << sizeof(chPtr) << '\n'; // prints 4
10 std::cout << sizeof(iPtr) << '\n'; // prints 4
11 std::cout << sizeof(somethingPtr) << '\n'; // prints 4

```

As you can see, the size of the pointer is always the same. This is because a pointer is just a memory address, and the number of bits needed to access a memory address on a given machine is always constant.

### What good are pointers?

At this point, pointers may seem a little silly, academic, or obtuse. Why use a pointer if we can just use the original variable?

It turns out that pointers are useful in many different cases:

- 1) Arrays are implemented using pointers. Pointers can be used to iterate through an array (as an alternative to array indices) (covered in lesson 6.8).
- 2) They are the only way you can dynamically allocate memory in C++ (covered in lesson 6.9). This is by far the most common use case for pointers.
- 3) They can be used to pass a large amount of data to a function in a way that doesn't involve copying the data, which is inefficient (covered in lesson 7.4)
- 4) They can be used to pass a function as a parameter to another function (covered in lesson 7.8).
- 5) They can be used to achieve polymorphism when dealing with inheritance (covered in lesson 12.1).
- 6) They can be used to have one struct/class point at another struct/class, to form a chain. This is useful in some more advanced data structures, such as linked lists and trees.

So there are actually a surprising number of uses for pointers. But don't worry if you don't understand what most of these are yet. Now that you understand what pointers are at a basic level, we can start taking an in-depth look at the various cases in which they're useful, which we'll do in subsequent lessons.

### Conclusion

Pointers are variables that hold a memory address. They can be dereferenced using the dereference operator (\*) to retrieve the value at the address they are holding. Dereferencing a garbage pointer may crash your application.

*Best practice: When declaring a pointer variable, put the asterisk next to the variable name.*

*Best practice: When declaring a function, put the asterisk of a pointer return value next to the type.*

### Quiz

- 1) What values does this program print? Assume a short is 2 bytes, and a 32-bit machine.

```

1  short value = 7; // &value = 0012FF60
2  short otherValue = 3; // &otherValue = 0012FF54
3
4  short *ptr = &value;
5
6  std::cout << &value << '\n';
7  std::cout << value << '\n';
8  std::cout << ptr << '\n';
9  std::cout << *ptr << '\n';
10 std::cout << '\n';

```

```
11
12 *ptr = 9;
13
14 std::cout << &value << '\n';
15 std::cout << value << '\n';
16 std::cout << ptr << '\n';
17 std::cout << *ptr << '\n';
18 std::cout << '\n';
19
20 ptr = &otherValue;
21
22 std::cout << &otherValue << '\n';
23 std::cout << otherValue << '\n';
24 std::cout << ptr << '\n';
25 std::cout << *ptr << '\n';
26 std::cout << '\n';
27
28 std::cout << sizeof(ptr) << '\n';
29 std::cout << sizeof(*ptr) << '\n';
```

### **Show Solution**

2) What's wrong with this snippet of code?

```
1 int value = 45;
2 int *ptr = &value; // declare a pointer and initialize with address of value
3 *ptr = &value; // assign address of value to ptr
```

By far the best explanation of pointer then anywhere else I have seen. Thanks a lot.

But just one point.

In my humble opinion pointer can be understood more clearly if we initialize a pointer as `int* pntr` rather than `int *pntr;`

As to initialize an integer we use:

```
Int x;
```

And then give it a value:

```
x=9;
```

Same way we initialize a pointer:

```
Int* pntr;
```

And give it a value:

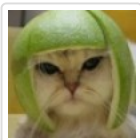

```
pntr=&x;
```

Now we dereference it (get the value at pointer address):

```
Int y=*pntr;
```

Result:

```
printf ("y= %d\n", y); // 9
```

Alex

I agree. The upcoming rewrite of this lesson will move the asterisk to be with the type rather than the variable name.

Charan

Hey,  
We don't usually pass an uninitialised variable as a function argument. Can we do that with pointer variable?

nascardriver  
December 24, 2019 at 2:50 am · Reply

You can, but you shouldn't. Same problem as with other variables.

**Georges Theodosiou**  
October 28, 2019 at 8:03 am · Reply

Dear NASCAR driver,  
Please let me ask you: do you confirm that following program means that we can reinitialize a pointer? Regards.

```

1  #include <iostream>
2
3  int main ()
4  {
5      int a{1};
6      int b{2};
7
8      int *c{&a};
9      int *d{&b};
10
11     std::cout << "pointer to a: " << c << '\n';
12     std::cout << "pointer to b: " << d << "\n\n";
13
14     c = {&b};
15
16     std::cout << "pointer to a after has been assigned &b: " << c << '\n';
17     std::cout << "pointer to b: " << d << "\n\n";
18
19     return 0;
20 }
```

nascardriver  
October 28, 2019 at 8:07 am · Reply

No. Line 14 is an assignment. Variables can only be initialized once, without exceptions.

**Georges Theodosiou**  
October 29, 2019 at 1:10 am · Reply

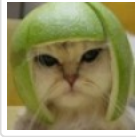

Dear NASCAR driver,  
Please accept my many thanks for you replied and many more for your - as usual - instructive answer. Regards.

October 16, 2019 at 1:04 am · Reply

Dear Teacher,  
Please let me point out that in first quiz variable name "value" is of same color as type "short",

object "cout", and operator "sizeof". Other variable names are of different color. Regards.

Alex

October 18, 2019 at 2:44 pm · Reply.

Must be a bug in the module that does the syntax highlighting. I've updated the variable name to something else so it colors correctly. Thanks!

**Georges Theodosiou**

October 11, 2019 at 1:24 am · Reply.

Dear NASCAR driver,

Please let me ask your instructive answer. Is \*ptr another name of the variable ptr is pointing to?

Regards.

**nascardriver**

October 11, 2019 at 1:56 am · Reply.

Yes

```
1 int i{ 123 };
2 int* p{ &i };
3 int& j{ *p };
4
5 j = 321;
6
7 std::cout << i << ' ' << *p << ' ' << j << '\n'; // 321 321 321
```

Dear Mr. NASCAR driver,

Please let me express my sincere thanks for you replied and that immediately.

However I have to learn references for understand your program. Regards.

**nascardriver**

October 11, 2019 at 4:05 am · Reply.

Oops, sorry, I thought they had been covered already.  
A reference is basically an alias for a variable.

**Georges Theodosiou**

October 12, 2019 at 2:11 am · Reply.

Dear NASCAR driver,

Please let me say you that after I have learned basics of lesson 6.11, I was able to understand your snippet. I added line

```
1 | std::cout << &i << ' ' << &*p << ' ' << &j << '\n'; // prints same adress
```

and it became clear that i, \*p, and j have same address, then are 3 names of some variable. Regards.

**Georges Theodosiou**October 9, 2019 at 6:52 am · Reply.

Dear Teacher,

Please permit me a suggestion: in the image below "Conceptually, you can think of the above snippet like this:" memory address should be below the right square so that left square points to address. Regards.

**Georges Theodosiou**September 20, 2019 at 1:34 am · Reply.

Dear Mr. NASCAR driver, please let me point out that pointer gets common variable's address even if it's not initialized. For example

```

1  #include <iostream>
2
3  int main()
4  {
5      int value;
6      int *ptr = &value;
7
8      std::cout << &value << '\n';
9      std::cout << ptr << '\n';
10
11     return 0;
12 }
```

Regards.

**nascar driver**September 20, 2019 at 1:39 am · Reply.

Correct. The value of the variable the pointer is pointing to doesn't matter.

**Benur21**August 29, 2019 at 1:13 pm · Reply.

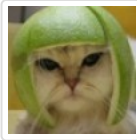

Why when I print a char pointer I get this? Shouldn't it print an address?

```

1  #include <iostream>
2
3  int main()
4  {
5      char value = '7';
6      char *ptr = &value;
7
8      std::cout << ptr << '\n';
9      std::cout << ptr+1 << '\n';
10     std::cout << ptr+2 << '\n';
11     std::cout << ptr+3 << '\n';
12
13     return 0;
14 }
```

```

1  7q
2  q
3  q
```

Alex

[September 1, 2019 at 2:29 pm · Reply](#)

std::cout treats char pointers as C-style strings and tries to print the result as a C-style null-terminated string. Since your pointer only points to a single character (7) that isn't null-terminated, it's printing garbage beyond the first character.

Benur21

[August 29, 2019 at 7:34 am · Reply](#)

In my system (Windows 10 and g++), addresses print like this: 0x71fecc

I saw a video, they guy kept saying that a pointer is just an integer. But in this tutorial you are claiming that a pointer is just a variable. Can you please elaborate which is true?

And is it also true that the type of a pointer doesn't change a thing about the size of a pointer? The pointer has always the same size (based on the number of bits of your computer)?

And the type decides how to interpret the value. So If we have the type integer: we can change the value because we know the pointer starts at an address, and the next 3 bytes belong to it?

**nascardriver**

[August 13, 2019 at 2:44 am · Reply](#)

Both are true. A pointer is a variable with an integer value.  
A pointer always has the same size.

Ilia Lyshev

[July 26, 2019 at 4:55 am · Reply](#)

Never ever put the asterisk next to variable name. Always put the asterisk next to type name, like `int* somePtr`.

Brandon

[July 27, 2019 at 11:28 pm · Reply](#)

More intuitive to put asterisk before the variable name because for example if you had the code - `int* x, y` - it seems like both x and y are pointers when that is not the case. `Int *x, y` makes it more obvious that x is a pointer and y is just an int making it the "better way", though both will work.

Miro

[January 5, 2020 at 2:49 am · Reply](#)

I think it should be

```
1 | int* varName;
```

as it is part of type definition, which is different than dereferencing operator

```
1 | *varName
```

which operate on variable

For the argumet about declaring more variables of same type in same line, that should be avoided anyway as it is better to declare each variables in it own line as it is easier to track changes with version control (git)
